# Supplemental Appendix for: "Scaling Data from Multiple Sources" 

Ted Enamorado* Gabriel López-Moctezuma ${ }^{\dagger} \quad$ Marc Ratkovic ${ }^{\ddagger}$

January 15, 2020

This supplemental appendix contains two sections. In the first, we describe the estimation procedure of our algorithm. The second presents additional results from our simulations and the main empirical application.

## A MD2S Estimation

Estimation proceeds in two steps. First, we recover estimates of the shared and idiosyncratic subspaces. Second, all the subspaces are partialed out of the data matrix. The aforementioned steps are fit for each dimension $q$.

$$
\text { Initialize } \hat{\mathbf{Z}}_{(1)}^{0}=l s v\left(\mathbf{Y}_{(1)}\right) ; \hat{\mathbf{Z}}_{(2)}^{0}=l s v\left(\mathbf{Y}_{(2)}\right) ; \hat{\mathbf{Z}}_{S}^{0}=l s v\left(\tilde{\mathbf{Y}}+\tilde{\mathbf{Y}}^{\top}\right) \text { where } \tilde{\mathbf{Y}}=\mathbf{Y}_{(1)} \mathbf{Y}_{(1)}^{\top} \mathbf{Y}_{(2)} \mathbf{Y}_{(2)}^{\top}
$$

Initialize $\mathbf{Y}_{(m)}^{0}=\mathbf{Y}_{(m)}$; where we denote as $l \operatorname{sv}(\mathbf{A})$ a function that extracts the first left singular value of the matrix $\mathbf{A}$.

1. Convergence in each subspace,

[^0](a) Update $\widehat{\mathbf{Z}}_{(m) ; q}$ for $m=1$ then $m=2$.
i. $\hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}=\operatorname{lsv}\left(\mathbf{M}\left(\hat{\mathbf{Z}}_{S}^{(t-1)}\right) \mathbf{Y}_{(m)}^{(t-1)}\right)$
ii. $\widehat{\mathbf{Z}}_{(m) ; q}^{(t)}=\frac{\left(\mathbf{H}\left(\mathbf{X}_{(m)} \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}\left(1-\gamma_{(m) ; q}\right)+\mathbf{M}\left(\mathbf{X}_{(m)} \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)} \gamma_{(m) ; q}\right)\right.\right.}{\left\|\mathbf{H}\left(\mathbf{X}_{(m)}\right) \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}\left(1-\gamma_{(m) ; q}\right)+\mathbf{M}\left(\mathbf{X}_{(m)}\right) \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)} \gamma_{(m) ; q}\right\|}$
where $\mathbf{X}_{(m)}$ represents a the matrix of covariates informing the $m$ th subspace and $\gamma_{(m) ; q}$ is estimated as the argmax of:
$$
\frac{\left(\mathbf { H } ( \mathbf { X } _ { ( m ) } \hat { \mathbf { Z } } _ { ( m ) | S ; q } ^ { ( t ) } ( 1 - \gamma ) + \mathbf { M } ( \mathbf { X } _ { ( m ) } ) \hat { \mathbf { Z } } _ { ( m ) | S ; q } ^ { ( t ) } \gamma ) ^ { \top } \mathbf { Y } _ { m } ^ { ( t - 1 ) } \mathbf { Y } _ { m } ^ { ( t - 1 ) \top } \left(\mathbf{H}\left(\mathbf{X}_{(m)} \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}(1-\gamma)+\mathbf{M}\left(\mathbf{X}_{(m)}\right) \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)} \gamma\right)\right.\right.}{\left\|\mathbf{H}\left(\mathbf{X}_{(m)}\right) \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}(1-\gamma)+\mathbf{M}\left(\mathbf{X}_{(m)}\right) \hat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)} \gamma\right\|^{2}}
$$

The parameter $\gamma_{(m) ; q}$ seeks to balance how much the covariates explain the data either by explaining $\mathbf{Z}_{(m) \mid S ; q}^{(t)}$ through the linear projection $\mathbf{H}\left(\mathbf{X}_{(m)}\right) \widehat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}$ or via the residual $\mathbf{M}\left(\mathbf{X}_{(m)}\right) \widehat{\mathbf{Z}}_{(m) \mid S ; q}^{(t)}$
(b) Update $\widehat{\mathbf{Z}}_{S ; q}^{(t)}$.
i. Update $\hat{\mathbf{Z}}_{S \mid 1 ; q}^{(t)}=l s v\left(\mathbf{M}\left(\hat{\mathbf{Z}}_{(1)}^{(t)}\right) \mathbf{Y}_{(1)}\right) ; \hat{\mathbf{Z}}_{S \mid 2 ; q}^{(t)}=\operatorname{lsv}\left(\mathbf{M}\left(\hat{\mathbf{Z}}_{(2)}^{(t)}\right) \mathbf{Y}_{(2)}\right)$
ii. Update $\widehat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)}=\left(\widehat{\mathbf{Z}}_{S \mid 1 ; q}^{(t)} v_{1 ; q}+\widehat{\mathbf{Z}}_{S \mid 2 ; q}^{(t)} v_{2 ; q}\right) /\left\|\widehat{\mathbf{Z}}_{S \mid 1 ; q}^{(t)} v_{1 ; q}+\widehat{\mathbf{Z}}_{S \mid 2 ; q}^{(t)} v_{2 ; q}\right\|$
where $\mathbf{X}_{S}$ represents the matrix of covariates informing the shared subspace and $v_{1 ; q}$ and $v_{2 ; q}$, with $v_{1 ; q}+v_{2 ; q}=1$, represent the weights balancing the proportion of information coming from each source which are estimated as the argmax of:

$$
\frac{\left(\widehat{\mathbf{Z}}_{S \mid 1 ; q}^{(t)}(1-v)+\widehat{\mathbf{Z}}_{S \mid 2 ; q}^{(t)} v\right)^{\top} \tilde{\mathbf{Y}}^{(t-1)}\left(\widehat{Z}_{S \mid 1 ; q}^{(t)}(1-v)+\widehat{\mathbf{Z}}_{S \mid 2 ; q}^{(t)} v\right)}{\left\|\widehat{\mathbf{Z}}_{S \mid 1 ; q}^{(t)}(1-v)+\widehat{\mathbf{Z}}_{S \mid 2 ; q}^{(t)} v\right\|^{2}}
$$

iii. Update $\widehat{\mathbf{Z}}_{S ; q}^{(t)}=\frac{\left(\mathbf{H}\left(\mathbf{X}_{S}\right) \hat{\mathbf{Z}}_{\mathbf{S} \mid 12 ; q}^{(t)}\left(1-\gamma_{S ; q}\right)+\mathbf{M}\left(\mathbf{X}_{S}\right) \hat{\mathbf{Z}}_{\mathbf{S}}^{(t)}{ }_{\mid 12 ; q} \gamma_{S ; q}\right)}{\left\|\mathbf{H}\left(\mathbf{X}_{S}\right) \widehat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)}\left(1-\gamma_{S ; q}\right)+\mathbf{M}\left(\mathbf{X}_{S}\right) \widehat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)} \gamma_{S ; q}\right\|}$
where $\gamma_{S ; q}$ is estimated as the argmax of:

$$
\frac{\left(\mathbf{H}\left(\mathbf{X}_{S}\right) \hat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)}(1-\gamma)+\mathbf{M}\left(\mathbf{X}_{S}\right) \widehat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)} \gamma\right)^{\top} \tilde{\mathbf{Y}}^{(t-1)}\left(\mathbf{H}\left(\mathbf{X}_{S}\right) \widehat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)}(1-\gamma)+\mathbf{M}\left(\mathbf{X}_{S}\right) \hat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)} \gamma\right)}{\left\|\mathbf{H}\left(\mathbf{X}_{S}\right) \hat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)}(1-\gamma)+\mathbf{M}\left(\mathbf{X}_{S}\right) \hat{\mathbf{Z}}_{S \mid 12 ; q}^{(t)} \gamma\right\|^{2}}
$$

We can give $\gamma_{S ; q}$ a mirror interpretation to the one given to $\gamma_{(m) ; q}$, but now we respect to

$$
\mathbf{Z}_{S \mid 12 ; q}^{(t)} \text { and } \tilde{\mathbf{Y}}^{(t-1)}
$$

2. After convergence in the previous step, update $\mathbf{Y}_{(m)}^{(t)}=\mathbf{M}\left(\left[\widehat{\mathbf{Z}}_{S ; q}, \widehat{\mathbf{Z}}_{(m) ; q}\right]\right) \mathbf{Y}_{(m)}^{(t-1)} \mathbf{M}\left(\left[\widehat{\mathbf{W}}_{(m) ; q}, \widehat{\mathbf{B}}_{(m) ; q}\right]\right)$ where $\widehat{\mathbf{W}}_{(m) ; q}=\mathbf{Y}_{(m)}^{\top} \widehat{\mathbf{Z}}_{S ; q}$ and $\widehat{\mathbf{B}}_{(m) ; q}=\mathbf{Y}_{(m)}^{\top} \widehat{\mathbf{Z}}_{(m) ; q}$, both normed to have length one.

## B Supplemental Results

## B. 1 Simulations: Bridging

As noted in the main text, our method can be used to combine information coming from different datasets.
One such instance of combining data is bridging across different actors. To assess the performance of the proposed method along that direction, we conduct an additional simulation study. The main difference with the other simulations is that the actors across datasets are allowed to differ and only common items between datasets are used to jointly scale the actors (bridging). ${ }^{1}$

The simulation setup is going to be quite similar. Again, the observed data consist of matrices $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$ with $N$ rows (common items) and $K_{(1)}$ (number of actors in dataset 1) and $K_{(2)}$ (number of actors in dataset 2) columns respectively. $N$ is varied along $\{50,500,1000\}$. For $K_{(1)}$ we have two scenarios. The first one we call it "balanced" as $K_{(1)}$ is set in $\{20,40,200\}$ and $K_{(2)}$ is chosen such that the ratio $K_{(1)}: K_{(2)}$ is equal to 2:3. In the second case, we varied $K_{(1)}$ along $\{10,20,100\}$ and $K_{(2)}$ is chosen such that the ratio $K_{(1)}: K_{(2)}$ is equal to $1: 4$. The latter is to mimic a situation where the number of actors in one dataset is significantly smaller if compared to the number of actors in the other dataset. As before, the data are generated according to equations (18) and (19) in the main text. All simulations were run 1,000 times.

As shown in Figure 1, MD2S does a remarkable job in terms of recovering the true ordering for each actor $\left(W_{m}\right)$. Similarly, the correlation between the true scaling and the estimates obtained from MD2S is almost perfect as both the number of actors and the number of items used to bridge increases. The latter is true even in the lopsided case. In table 1 we compare MD2S to multidimensional scaling (MDS) as implemented in the R-package smacof. For MDS we bridge estimates by pooling datasets. ${ }^{2}$ As table 1

[^1]shows, MD2S recovers the estimates that correlate highly with true actors' subspace and its precision grows with the number of common items to bridge. In contrast, MDS does not recover a the true actors' subspace and its performance decreases as the number of actors increases.

We believe these are promising results to motivate additional tests of the bridging capabilities of MD2S - which offers a built-in approach when there are common items across datasets. A main advantage of MD2S over previous alternatives is that pooling the datasets is not needed. For MD2S bridging is a consequence of assuming that common items between datasets exist and that these items connect the scaled positions of the actors. Furthermore, through the dimension weights and the idiosyncratic subspaces, MD2S provides a more flexible approach to address the "constant behavior" assumption which requires that actors across datasets face the same concerns when referring to a particular issue. ${ }^{3}$ However, having common items to bridge might not be an possibility in some situations, making bridging an impossible task in our framework. We leave for future research a thorough evaluation of the bridging properties of MD2S.
nature of values each observation in our simulated datasets take, we use MDS as a reference point.
${ }^{3}$ See the work of Lewis and Tausanovitch (2015) for a literature review of the bridging literature and a formal set of tests for the "constant behavior" assumption across other scaling models.

Panel (a) Balanced Number of Actors i.e., ratio $K_{(1)}: K_{(2)}$ is 2:3
Simulations: Bridging Different Actors Across Two Datasets

Panel (b) Lopsided Number of Actors i.e., ratio $K_{(1)}: K_{(2)}$ is 1:4
Simulations: Bridging Different Actors Across Two Datasets

Figure 1: Correlation between the True Actors' Subspaces ( $\mathbf{W}_{(m)}$ ) and their Corresponding MD2S estimates. Number of common items used to bridge datasets is $(N \in\{50,500,1000\})$ and the number of distinct actors in each dataset is set to $\left(K_{(1)}, K_{(2)}\right) \in\{(20,30),(40,60),(200,300)\}$ in panel (a) and to $\left(K_{(1)}, K_{(2)}\right) \in\{(10,40),(20,80),(100,400)\}$. The total number of actors represents the sum of $K_{(1)}$ and $K_{(2)}$. The $y$-axis ranges from 0 to 1 and measures the correlation between the true and estimated values across 1000 simulations per combination of $N$ and $K_{(1)}$. As in the simulations presented in the main text, MD2S does a remarkable job in terms of recovering the true ordering for each actor. In addition, MD2S improves its performance in the number of actors and the number of items used to bridge.

|  | MD2S |  |  | MDS |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Mean | 2.5\% | 97.5\% | Mean | 2.5\% | 97.5\% |
| 50 Items |  |  |  |  |  |  |
| 50 Actors | 0.88 | 0.68 | 0.97 | 0.27 | 0.02 | 0.69 |
| 100 Actors | 0.90 | 0.74 | 0.97 | 0.21 | 0.01 | 0.56 |
| 500 Actors | 0.91 | 0.79 | 0.97 | 0.16 | 0.01 | 0.43 |
| 500 Items |  |  |  |  |  |  |
| 50 Actors | 0.96 | 0.90 | 0.99 | 0.26 | 0.01 | 0.65 |
| 100 Actors | 0.97 | 0.94 | 0.99 | 0.19 | 0.00 | 0.51 |
| 500 Actors | 0.98 | 0.97 | 0.99 | 0.11 | 0.00 | 0.33 |
| 1000 Items |  |  |  |  |  |  |
| 50 Actors | 0.97 | 0.91 | 0.99 | 0.28 | 0.01 | 0.63 |
| 100 Actors | 0.98 | 0.95 | 0.99 | 0.22 | 0.01 | 0.52 |
| 500 Actors | 0.99 | 0.98 | 1.00 | 0.11 | 0.00 | 0.34 |

Table 1: Correlation between the True Actors' Subspaces ( $\mathbf{W}_{(m)}$ ) and their Corresponding MD2S and MDS estimates. Number of common items used to bridge datasets is $(N \in\{50,500,1000\})$ and the number of distinct actors in each dataset is set to $\left(K_{(1)}, K_{(2)}\right) \in\{(20,30),(40,60),(200,300)\}$. The total number of actors represents the sum of $K_{(1)}$ and $K_{(2)}$. As in the simulations presented in the main text, MD2S performs well in terms of recovering the true ordering for each actor. In the case of MDS, it does not perform as well and as the number of actors increases its performance decreases.

## B. 2 Simulations: Sparsity

While in some settings of our simulations we mimic the large size of a document term matrix, sparsity (a common feature of text data) is not accounted for in the main results. In this simulation study, we replicate our original simulation setting with $N=100, K_{(1)}=40, K_{(2)}=5000$ but we add sparsity (completely at random) to $\mathbf{Y}_{(2)}$ according to three levels: $20 \%, 50 \%$, and $80 \%$. As shown in figure 2, the performance of all scaling methods decrease with the degree of sparsity. However, it is worth nothing that even for high levels of sparsity, MD2S outperforms V-BIBFA and INDSCAL methods.

Figure 2: Scaled Locations Across Levels of Sparsity.

## B. 3 Simulations: Correlation Across Dimensions within Subspaces

In this simulation, we add different levels of correlations between the dimensions of each subspace. In particular, we use three levels: 0.20 (low), 0.50 (medium), and 0.80 (high) and set $N=100, K_{(1)}=40$,
$K_{(2)}=2500$. As shown in figure 3, the performance of M2DS is not affected by increasing the correlation across the dimensions within a subspace. While even for high of correlation MD2S outperforms the alternatives, it is worth noting that V-BIBFA performs as well as MD2S as the correlation between the dimensions within each subspace gets larger.

Panel (b): Idiosyncratic Subspace $\boldsymbol{Y}_{(1)}$

Panel (c): Idiosyncratic Subspace $\boldsymbol{Y}_{(2)}$

Figure 3: Scaled Locations Across Levels of Correlation between the Dimensions of each Subspace.

## B. 4 Simulations: Average Correlation Across Simulations

Tables (2), (3), and (4) present the average correlation across each of the simulation scenarios presented in Figures 1 and 2 in the main text.

|  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: |

Table 4: Average Correlation Across Simulations: Idiosyncratic Subspace $\mathbf{Y}_{(2)}$ •

## B. 5 Combining Senate Rollcall and Text Data.

## B.5.1 Estimates from MD2S without Senator-level Covariates

Figure (4) through (6) reproduce the results presented in the main text, with the sole difference that covariates are not used to inform each of the subspaces obtained from MD2S. The shared subspace and the idiosyncratic subspace for speech are substantively the same regardless whether we include covariates or not. The ranking obtained from the idiosyncratic subspace informed by the roll call data is slightly different when we omit covariates from the estimation stage. Again, we have conservative senators like DeMint, Lee, Toomey, Paul, and Risch, on one extreme, while the remaining Senators from the Republican party are located on the other. Thus, the idiosyncratic subspace obtained from vote data, again, reveals a party divide among Republicans.

Figure 4: Shared Subspace Locations Estimated via MD2S for the Members of the 112th U.S. Senate.

Figure 5: Idiosyncratic Vote Subspace Locations Estimated via MD2S for the Members of the 112th U.S. Senate.

Figure 6: Idiosyncratic Word Subspace Locations Estimated via MD2S for the Members of the 112th U.S. Senate. First Dimension.

## B.5.2 Different Levels of Sparsity

In this subsection we present evidence that our method is robust to several pre-processing steps when working with text data, namely whether we use unigrams and bigrams, and how we trim sparse terms from the term-document matrix (with low, medium, and high levels of sparsity in the term document matrix). As shown in table 5 across the six settings (\{unigram, bigram $\} \times\{l o w, m e d, h i\}$ ), the correlations across the first-dimension estimates are no lower than 0.9 for the shared subspace, 0.97 for the vote idiosyncratic subspace, and 0.86 in the word idiosyncratic subspace.

|  |  | Unigrams and Bigrams |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  | Levels of Sparsity |  |  |
|  |  | (High, Medium) | (High, Low) | (Medium, Low) |
| Shared subspace | correlation | 0.98 | 0.91 | 0.97 |
| Word subspace | correlation | 0.95 | 0.86 | 0.97 |
| Vote subspace | correlation | 0.99 | 0.97 | 0.98 |
|  |  | Unigrams only |  |  |
|  |  | Levels of Sparsity |  |  |
|  |  | (High, Medium) | (High, Low) | (Medium, Low) |
| Shared subspace | correlation | 0.99 | 0.95 | 0.98 |
| Word subspace | correlation | 0.96 | 0.87 | 0.97 |
| Vote subspace | correlation | 0.99 | 0.96 | 0.98 |

Table 5: Correlations Between Subspaces (1st Dimension) for Different Levels of Sparsity across the Document-Term Matrix. Low sparsity is equal to removing terms that are not used by at least 20 senators for a total of 1852 terms. Medium sparsity is equal to removing terms that are not used by at least 30 senators for a total of 2616 and High sparsity is equal to removing terms that are not used by at least 40 senators for a total of 3622 terms.

## B.5.3 Correlations Across Different Scaling Methods

Table (6) and figure (7) present the overall and within-party correlation across different scaling methods, respectively. First, all scaling methods separate Senators in two clusters (by party). Second, both both MD2S and SFA recover the same set of moderate and extreme senators within each party, consistent with the results of IDEAL and DW-Nominate. Third, jointly incorporating votes and floor speech introduces some variation in senators' rakings within party. For instance, republican Senators such as Sessions and

Kyl are found to be more extreme when combining vote and text data, than their scaled locations using only votes.

|  | Votes Only: |  |  | Votes and Words: |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | DW- <br> Nominate | IDEAL | MDS | SFA | MD2S | INDSCAL |
| Votes Only: |  |  |  |  |  |  |
| DW-Nominate | 1.00 |  |  |  |  |  |
| IDEAL | 0.99 | 1.00 |  |  |  |  |
| MDS | 0.98 | 0.98 | 1.00 |  |  |  |
| Votes and Words: |  |  |  |  |  |  |
| SFA | 0.93 | 0.93 | 0.95 | 1.00 |  |  |
| MD2S | 0.94 | 0.95 | 0.96 | 0.97 | 1.00 |  |
| INDSCAL | 0.48 | 0.47 | 0.43 | 0.30 | 0.38 | 1.00 |

Table 6: Correlations Across Different Scaling Methods for the 112th U.S. Senate. Votes Only refers to scaling methods that use roll call data, while Votes and Words refers to those scaling methods that use both roll call and speech data. The correlations presented here are calculated using the first dimension recovered by each method. In the case of MDS and INDSCAL we have reduced the roll call data to a dissimilarity matrix using a renormalized version of the Manhattan distance (L1 norm) between each pair of rows. The normalization factor is the number of columns in the roll call data, thus our our dissimilarity measure tells us the share of times two legislators vote in the same way. Similarly, for INDSCAL (Votes and Words) we have reduced the vote and speech data to two dissimilarity matrices (one per data set) using the same renormalized distance between rows. In the case of MD2S, we use the shared subspace. The table shows that traditional methods to scale the U.S. Congress, like IDEAL, DW-Nominate and MDS, correlate almost perfectly with SFA, and MD2S. In contrast, if we use votes and speech data, INDSCAL recovers a subspace does not correlate as well with the other alternatives.

Panel (a): MD2S

Panel (b): SFA

Panel (c): INDSCAL

Figure 7: Scaled Locations and Partisanship. The three panels above present the results comparing MD2S, SFA, and INDSCAL to traditional scaling methods such as DW Nominate, Ideal, and MDS. As the three panels show, MD2S recovers a shared subspace that overall correlate well with scaling methods that use only vote data. Not only that, MD2S separates Senators' in two clusters (partisanship). SFA also performs well when compared to traditional methods and INDSCAL produces estimates that are not as highly correlated with the aforementioned traditional approaches - producing at least three clusters of Senators.

## B.5.4 Bootstrap Estimates

Figure (8) through (10) present the $95 \%$ percentile confidence intervals obtained via the non-parametric bootstrap (5000 replications) described in Section 3.5.

Figure 8: Bootstrap Confidence Intervals for the Shared Subspace Locations Estimated via MD2S for the Members of the $\mathbf{1 1 2 t h}$ U.S. Senate.

Figure 9: Bootstrap Confidence Intervals for Idiosyncratic Vote Subspace Locations Estimated via MD2S for the Members of the 112th U.S. Senate.

Figure 10: Bootstrap Confidence Intervals for Idiosyncratic Word Subspace Locations Estimated via MD2S for the Members of the 112th U.S. Senate. First Dimension.

## B.5.5 Correlation of Subspaces with Covariates

Table (7) presents the estimated coeficients associated with Senators' covariates that inform the estimated subspaces in Section 5 of the main text. Note that uncertainty for these covariates can be assessed via non-parametric bootstrap.

Table 7: Correlation with Covariates

|  | Dependent variable: |  |  |
| :--- | :---: | :---: | :---: |
|  | Shared | Votes | Words |
|  | $(1)$ | $(2)$ | $(3)$ |
| party | -0.1870 | -0.0540 | -0.0180 |
| gender | 0.0220 | 0.0660 | -0.0310 |
| seniority | -0.0003 | 0.0030 | -0.0020 |
| membership | 0.00001 | 0.0004 | -0.0060 |
| agricultural | 0.0060 | -0.1100 | 0.0680 |
| economics | 0.0110 | 0.0130 | 0.0340 |
| security | -0.0090 | 0.0940 | -0.0670 |
| leadership | 0.0030 | 0.1010 | 0.0140 |
| Constant | 0.0860 | -0.0670 | 0.0540 |
| Observations | 101 | 101 | 101 |
